Abstract
Emergency pancreatico-duodenectomy (EPD) is a very rare procedure and few reports are present in medical literature. It is an uncommon approach, usually
used for emergency surgical treatment of abdominal trauma that involves the head of the pancreas or the duodenum, but it is also a surgical tool for the treatment of ruptured aneurysms, bleeding pseudocysts, duodenal perforations, uncontrollable hemorrhage from ulcers and tumors, severe infectious complications of acute pancreatitis or endoscopic retrograde cholangiopancreatography related complications (1,2). It is rarely used as the first line of treatment in case of acute bleeding from arterial pseudoaneurysm of the cephalic region of the pancreas. We present the case of a bleeding pseudoaneurysm of the cephalic region of the pancreas in a young patient with previously undiagnosed chronic pancreatitis and with suspicion of a malignant process located in the head of the pancreas. We performed a pancreaticoduodenectomy with resection of superior mesenteric and portal vein with reconstruction using Gore-Tex® vascular graft due to probable venous abutment. Postoperative course was without any major complications, only minor grade-I pancreatic fistula was present. We determine that EPD is a useful tool in the treatment of such cases. It can be used as a first line of treatment or secondary to endovascular stenting or embolization.

**Key words:** pancreatico-duodenectomy, vascular resection, emergency pancreatic resection, vascular reconstruction

---

**Introduction**

Pancreatico-duodenectomy (PD) is one of the most demanding surgical procedures and was first described by Whipple in 1935 for the treatment of periampullary tumors. Routinely, PD is performed as an elective procedure and over the years it became a relatively safe surgical procedure that is performed safely with low mortality and morbidity rates.

One can not find many reports of EPD for non-trauma patients and related literature is limited by the number of cases.

EPD represents less than 2 % of indications, but associates an increased risk for the patient and added challenge for the surgeon (1).

One of the rare complications of chronic pancreatitis is arterial pseudo-aneurysm of the pancreatic or peri-pancreatic arteries into a pseudocyst with upper gastrointestinal bleeding. In the majority of cases they are situated in the body and tail of the pancreas and the splenic artery is involved (more than 50% of cases) but can also involve the gastro-duodenal artery, the pancreatico-duodenal artery or the hepatic artery (common hepatic artery, replaced or accessory right hepatic artery from the superior mesenteric artery). It is a life threatening complication with mortality of over 12 % in treated patients and over 90% in patients left untreated.

Enhanced computed tomography is routinely used for the diagnosis of this pathology. It can describe the location of the pseudocyst, the artery involved in the pseudo-aneurysm and determine contact with surrounding structures (blood vessels, adjacent organs).

Endoscopic ultrasound can also be useful for preoperative evaluation.

It can:

- describe the pseudocyst,
- pin point the originating artery,
- describe contact with surrounding organs and vessels,
- determine the point of communication between the digestive tract and the pseudo-cyst through which the blood is expelled into the digestive tract.

After thorough evaluation, the first line of treatment is endovascular trans-arterial embolization or stenting of the involved artery. No evidence based guidelines are present so we can not present embolization or stenting as a concrete treatment or as a bridge therapy toward definitive surgical treatment. If the need for laparotomy is present the first surgical treatment is the ligation of the originating artery involved. This can only be done if the source of the bleeding is linked to a singular artery not to a network.

**Case report**

A 29 year old male non-smoker, that occasionally consumed alcohol, who presented a minor pancreatic reaction 8 months prior to the debut of symptomatology was investigated for melenic stools after consuming pain killers.

Lab works, at the time of presentation in another medical facility, described anemia with hemoglobin of 9 g/dl, a hematocrit level of 22 % with normal hepatic, renal and coagulation tests. No signs of acute pancreatitis were present.

Upper gastrointestinal endoscopy did not reveal any signs of acute bleeding.

An enhanced CT exam was performed. It revealed an enlarged pancreatic area with a dilated pancreatic duct, multiple micro-calcifications and cysts. In the cephalic region of the pancreas a well circumscribed mass of 60 by 55 mm was identified.
After the contrast was injected the center of the mass presented the same intensity as the venous structures, a clear sign of vascular involvement and intratumoral bleeding. At the edge of the mass multiple micro-calcifications were present. The tumor mass was in close contact with the portal vein and the spleno-portal confluent compressing and narrowing their circumference.

After completing these investigations, in a regional hospital, the patient was referred to our center of surgery for complete evaluation and curative treatment.

At the moment of the initial evaluation the patient presented no signs of acute upper GI bleeding, had a heart rate of 80 bpm, a blood pressure of 120 over 75 mmHg, with a hemoglobin level of 8.8 g/dl, hematocrit of 24%, normal liver enzymes, normal renal function and no signs of a pancreatic reaction. All coagulation tests were normal. Tumoral markers CEA and CA 19-9 were within normal range.

Our radiological team reevaluated the CT exam, previously performed. They described an enlarged pancreas due to chronic pancreatitis with calcifications present through the pancreatic region, multiple cysts and an enlarged pancreatic duct at the level of the body and tail. In the head of the pancreas a cystic tumoral mass of 60 by 55 mm was described. The tumor presented, in the center of it, signs of bleeding due to a communication with one of the arterial branches of the pancreatic head arterial network. The origin of the bleeding arterial branch, from the superior mesenteric artery or the celiac trunk, can not be determined for certain. The tumor was in close contact with the superior mesenteric artery and the spleno-portal junction, determining an important narrowing of their circumference. A malignant tumor with venous abutment can not be ruled out, so the patient continued to be investigated for elective radical surgery (Figs. 1-4).

The interventional radiologist evaluated the possibility of endovascular stenting or embolization. This therapeutic approach can’t be used in this case because of the inability to determine the bleeding arterial branch and due to the suspicion of malignancy.

An upper GI endoscopy was performed and did not reveal any significant findings.

An ultrasound evaluation confirmed all of the CT exam findings. And showed no signs of evolutive disease.

During the first 5 days of hospital stay the patient presented some melenic stools, with a constant hemoglobin level without the need for blood transfusions. On the 6-th day of hospitalization the patient presented a sudden loss of consciousness followed by haematemesis of approximately 750 cc. A hemoglobin value of 6 g/dl was found. Heart rate spiked to 120 bpm and blood pressure dropped to 100 over 50 mmHg. Ultrasound showed no signs of intra-abdominal bleeding. A nasogastric tube was placed, and fresh blood was exteriorized. A vivid resuscitation using blood products was initiated. Three units of packed blood cells were used but the hemoglobin level increased only to 7 g per dl and approximately 500 cc of fresh blood was

**Figure 1.** CT exam – dilated pancreatic duct. Portal vein and splenic vein appear normal at this level

**Figure 2.** CT exam – after contrast is injected signs of active bleeding in the tumoral mass are present. It also shows compression on superior mesenteric vein and portal vein. Tumoral abutment to this venous structures can not be excluded. The origin of the superior mesenteric artery appear not to be involved in the tumoral mass originating in the head of the pancreas
Taking into consideration the suspicion of a cystic pancreatic malignant tumor that has communication with the digestive tract and active bleeding, as the source for haematemesis, with no other alternative ways of treatment, we proceeded towards a surgical intervention, most probably an emergency pancreaticoduodenectomy.

Intraoperative exploration revealed an enlarged and hard pancreatic head due to chronic pancreatitis and to the presence of an atumoral mass of 60 by 60 mm that apparently had no distinct limits from the superior mesenteric vein and the spleno-portal junction. A posterior approach was used in order to determine superior mesenteric artery involvement. No contact with the superior mesenteric artery was present both at its origin from the aorta and through its retropancreatic route.

The inferior and superior limits of tumor invasion in the superior mesenteric vein and portal vein were identified and placed onto plastic straps. The spleno-portal junction was clearly identified and the splenic vein was sectioned and sutured.

After performing a classic Whipple procedure the head of the pancreas was left hanging on its venous abutment of the superior mesenteric vein, spleno-portal junction and portal vein. A 5 centimeters venous resection was performed that included the spleno-portal junction. Inspite of liver mobilisation, from its diaphragmatic adherences and the mesentery of the small intestine, we weren’t able to perform a mesenterico-portal anastomosis in good conditions.

In this point, the operative surgeon opted for venous reconstruction using a Gore-Tex® vascular graft. After the venous reconstruction an intraoperative Doppler-ultrasound was performed in order to determine flow rates through the venous graft to the liver. A blood velocity of 22 cm per second was determined by Doppler-US in the liver. Using this type of graft an adequate venous caliber was obtained and special care was taken in positioning the graft in order to prevent kinking or twisting (Fig. 5).

We continued with the other anastomoses in a classic manner (pancreatico-jejunal anastomosis...
using the Büchler technique, one layer of running PDS 5-0 end-to-side hepatico-jejunal anastomosis at 30 cm distance from the pancreatico-jejunal anastomosis, and a running to layer PDS 4-0 end-to-side retrocolic gastro-jejunal anastomosis at another 30-35 cm from the hepatico-jejunal anastomosis).

The operative time was of 300 minutes and a total number of 7 blood units were used in order to resuscitate the patient. The total time of venous vascular occlusion was less than 20 minutes, so bowel edema was minimal and therefore was no need for superior mesenteric artery temporary occlusion in order to prevent it.

After surgery the patient was admitted in the Intensive Care Unit.

Postoperative course was simple in the first six postop days using "fast track" feeding techniques. No signs of pancreatitis were present. Portal flow was evaluated on a daily basis using Doppler-ultrasound. A heparin perfusion was kept for 7 days in order to prevent graft thrombosis. After the 7-th postop day 75 mg of aspirin were administered on a daily dose. Amylase and lipase levels were dosed from the intra-abdominal drainage tubes on a daily routine and showed, in the 5-th postop day, a value three times the blood level. In the sixth postop day a pancreatic leakage of 40 cc was exteriorized through one of the peri-pancreatic drainage tubes.

A contrast enhanced CT exam was performed to determine the flow through the vascular graft and to evaluate the abdominal cavity in order to exclude any collections. No signs of portal vein, graft or SMV thrombosis were found and a good blood flow was determined in the intrahepatic portal branches (Figs. 6, 7, 8).

The pancreatic leakage reduced its volume progressively and the drainage tube was extracted in the 12-th postop day.

The patient was discharged in the 14-th postop day with oral antiaggregant therapy.

The final pathological exam revealed chronic pancreatitis with signs of acute pancreatic reaction. Multiple cysts and calcifications were presents. One of the cyst presented signs of intracystic bleeding and a communication with the posterior wall of the duodenum. One of the arterial branches that was located near the cyst had a perforated pseudoaneurysm. The suspicion for malignancy was ruled out (Fig. 9). The resected venous segments had no clear margins from the cystic tumoral process so a limited resection wasn’t feasible (Fig. 10). The common bile duct was dilated and involved in the cystic process (Fig. 11).

Discussions

Pancreatice-duodenectomy is a complex surgical pro-
procedure, in the majority of cases, performed in an elective setting, with a stable patient, investigated according to pre-op and oncological protocols and using standardized surgical techniques. Depending on the number of pancreatico-duodenectomies performed, high-volume-centers report a low morbidity rate and a mortality rate of less than 3-5%. Major postoperative complication are delayed gastric emptying, pancreatic fistula, bile leak, surgical site infection, intra-abdominal bleeding, pancreatitis, cholangitis and marginal ulcers (1,3,4). If you add portal and/or mesenteric vein resection with reconstruction morbidity and mortality rates spike.

Emergency pancreatico-duodenectomy is quite exceptional. It represents less than 2% of the total number of pancreatico-duodenectomies (5). In the majority of cases, it is performed for grade V traumatic lesions of the head of the pancreas or of the duodenum in whichlesser procedures are not possible (5). Major vascular involvement can be associated with vascular reconstruction procedures such as mesenteric vein resection and reconstruction using alloplastic patches or synthetic grafts. Arterial lesions can be solved by in situ sutures, reconstruction using vascular grafts or reimplantation of the celiac trunk or superior mesenteric artery in the aorta.

In non trauma patients an EPD is performed for severe complications after therapeutical endoscopies, endoscopic retrograde cholangiopancreatography related complications, ruptured aneurysms, bleeding pseudocysts, duodenal perforations, uncontrollable hemorrhage from ulcers and tumors, severe infectious complications of acute pancreatitis (1).

For pre-operative evaluation of these patients there isn’t a standardized protocol. In the majority of cases a contrast enhanced CT scan is used and provides significant information. An upper GI endoscopy can reveal the source of the bleeding or the orifice through which blood is expelled in to the digestive tract.

Upper GI angiography can be useful for diagnosis and therapeutic maneuvers (4).

For the treatment of massive upper GI bleeding, originating from the pancreatico-duodenal region, the first line of treatment may include endoscopic maneuvers such as the injection of epinephrine, laser coagulation or mechanical occlusion of bleeding sites using clips. Interventional radiology maneuvers such as selective arterial embolization, intra-arterial vasopressin injection or arterial stenting, can also be powerful treatment tools with curative results.

Surgical treatment is thus performed when these procedures fail (4). Fancy investigation techniques as well as minimally invasive procedures are dependent on
the endowment of the hospital. In many emergency hospitals these investigations or procedures can not be performed 24/7, or the patient does not have the time to be subjected to such time consuming investigations. Depending on the quantity of blood loss the patient can be unstable, hypothermic, suffer from acidosis and coagulation deficit. In this case the surgeon is compelled to take action and an EPD can save the patients life.

Centers with experience in pancreatic surgery, vascular resections and vascular reconstruction can provide a higher rate of success. The morbidity and mortality rates are directly related to the number of procedures performed in that center and on the surgeons experience in HPB surgery and vascular resection and reconstruction. A surgical team familiar with HPB surgery can adapt to the emergency situation and also provide better postoperative care because it is customized with post-op complications and can treat them accordingly. Interdisciplinary communication and expertise can provide better outcomes (6,7).

Regarding the operative technique, no specific protocol or preferred approach can be found. The surgeon is forced by the emergency context to rapidly control bleeding and reduce contamination of the abdominal cavity. If vascular involvement is found a quick decision needs to be taken and a surgical solution found. Regarding pancreatic reconstruction a one stage or two stage approach can be used. (exterior stenting of the pancreatic duct). Biliary and gastric anastomoses are recommended to be performed in a one stage procedure.

Prognosis depends on the timing to intervention, the experience of the operating surgeon, on the peri- and postoperative anesthesiological management and on the radiological management of postoperative complications (6,7).

Surgical resection offers the only potential cure for HPB malignant tumors, but many of these patients are diagnosed with locally advanced tumors that involve the mesenteric vasculature, particularly the superior mesenteric vein, portal vein and spleno-portal junction. With current multidisciplinary management (neoadjuvant chemotherapy and radiation) these patients can benefit from en bloc vascular resection and this approach became standard of care in many high volume centers, where approximately 20-40% are treated by PD with en bloc venous resection and a 98% R0 rate is achieved (3,8).

If vascular involvement is identified preoperatively concomitant en bloc vascular resection has been shown to result in lower rates of positive margins in comparison to unplanned resections (9). In this particular case a R1 or R2 resection were looked upon as good results considering the risk for immediate death due to massive bleeding from the cystic tumor.

The decision regarding the type of conduit used for venous reconstruction is multifactorial but the main objective is to obtain a tension-free anastomosis (9).

In this particular case a certain neoplastic or benign tumor diagnosis could not be established preoperatively so the operative surgeon was prepared for vascular resection and reconstruction in order to obtain an R0 resection.

Surgery related complications after EPD are mainly the same as those for the elective procedure. Complications related to acidosis, hemodynamic shock, coagulation deficit and hypothermia are increasing the morbidity and mortality rates after EPD.

All of these rates are increased by vascular resection and reconstruction.

Conclusion

This case demonstrates the feasibility of EPD with venous resection and reconstruction in attempt to save the life of a patient with acute massive bleeding from a potentially malignant tumor located in the head of the pancreas. In the case of life threatening bleeding, that can not be solved by minimally invasive approach (endovascular stenting or embolization), emergency pancreatico-duodenectomy can become a useful tool that can help save the life of the patient. In specialized centers with surgeons specialized in HPB surgery and vascular reconstruction even borderline resectable tumors with venous involvement can benefit from surgical treatment with curative intent.
