Rezumat

Tromboprofilaxia la pacienții vârstnici: statusul actual și considerații pentru viitor

Tromboembolismul venos reprezintă cea mai frecventă cauză evitabilă de deces în rândul pacienților spitalizați. Pacienții vârstnici care suferă intervenții operatorii în sfera Chirurgiei Generale prezintă o susceptibilitate crescută pentru Tromboza Venoasă Profundă /Tromboembolism Pulmonar Acut (TVP/TEPA). Riscul de TVP/TEPA crește de altfel adițional în prezența comorbidităților prevalente în grupul pacienților vârstnici. Cu toate acestea, TVP/TEPA este de multe ori subdiagnosticat și subtratat în acest grup de pacienți. În prezent există o serie de scoruri de risc clinice care clasifică pacienții în categorii de risc scăzut/moderat/crescut pentru Tromboprofilaxie propun fie o combinație de procedee mecanice (ciorapi elastici sau compresie gambieră penumatică intermitentă), fie agenți farmacologici (ex. Heparina cu greutate moleculară redusă sau anticoagulante orale). Dat fiind faptul că riscul de săngerare ca efect secundar al tratamentului reprezintă o cauză semnificativă de îngrijorare în ceea ce privește populația vârstnică, metodele de tromboprofilaxie trebuie ajustate astfel încât acest risc sa fie cât mai scăzut. Atât opțiunea pentru un anumit tromboprofilactic, cât și doza acestuia pot fi, de asemenea, influențate de o alterare a funcției renale. Durata necesară tromboprofilaxiei este încă neclară, ea putând varia între c. o săptămână și o lună, în funcție de patologia pacientului și evaluarea riscului individual de TVP/TEPA.

Cuvinte cheie: tromboembolism venos, pacienții geriatrici/vârstnici, tromboprofilaxie
Abstract
Venous thromboembolism is the number one cause of preventable death for hospital inpatients. Aging general surgical patients are especially susceptible to DVT/PE and this risk increases in the presence of other comorbidities prevalent in the elderly. However, it is often unrecognised and undertreated. Various risk scores classify patients in low, moderate and high risk categories. Current guidelines for thromboprophylaxis advocate combination of mechanical methods in the form of elastic stockings or intermittent pneumatic leg compression and pharmacological agents such as low molecular weight heparins and oral anticoagulants. Increased bleeding risk is a concern in this population and the method of prophylaxis needs to be adjusted as a result. Decreased renal function also influences the choice and dosage of medication. The required duration of prophylaxis is unclear but can range from one week to more than a month depending on the underlying pathology and individual risk assessment.

Key words: venous thromboembolism, elderly, thromboprophylaxis

Introduction
Each year, approximately 1,000,000 Americans suffer a venous thromboembolic (VTE) event—deep vein thrombosis (DVT) and/or pulmonary embolism (PE) and 100,000 deaths occur as a result.

Venous thromboembolism is therefore estimated to account for 5–10% of all deaths among hospitalised patients and is classified as the most common cause of preventable death.

At the same time VTE stands as one of the most significant causes of peri-operative mortality. If left without prophylaxis, approximately 20-25% of general surgical patients will develop DVT/PE and more than 2% will suffer significant complications from it (1,2).

One of the most obscure aspects of venous thrombosis risk is advancing age. The incidence of venous thromboembolism increases incrementally with age, reaching >21% over the age of 65 versus <2 % for those younger than 45 (2-5).

What is more, this population presents more frequently with PE on a background of DVT and also has increased mortality attributed to the disease compared to younger patients.

In the surgical setting especially, VTE occurs in 65% of patients over 70 years without prophylaxis and 16% of patients over 80 years die early after the diagnosis of VTE in comparison with 2% before 40 years (2,6,7).

It is therefore worrisome that this risk often remains unrecognised and elderly patients rarely receive appropriate prophylaxis. With the number of aging individuals undergoing major abdominal surgery raising exponentially, this represents a significant healthcare issue.

In this review, we focus on elderly general surgical patients. We summarise the pathophysiology and risk factors that predispose this group to DVT/PE along with the current guidelines for thromboprophylaxis and consider the controversies and questions that require further investigation.

Epidemiology and Risk Factors
Age itself has been shown to be an independent risk factor for DVT/PE, likely secondary to pathophysiological changes resulting in a hypercoagulable state. Chronic inflammation, age-related changes in the micro-circulation, cellular response to drugs and the presence of cell-derived micro-particles that trigger the coagulation cascade increase susceptibility to deep vein thrombosis (8-10).

In addition to that, elderly patients often have reduced mobility and venous stasis as a result. They also suffer from co-morbidities known to promote VTE (peripheral vascular
disease, COPD, ischaemic heart disease and heart failure, malignancy, fractures) (11-13).

In combination with the significant tissue trauma associated with surgery, all components of Virchow’s classic thrombotic triad are present (Table 1).

Unfortunately, the real risk of VTE in this population remains unrecognized by many clinicians. When combined with the fear that thromboprophylaxis medication will lead to significant bleeding, older patients are often left un- or under-protected from thromboembolic disease while in hospital.

Studies of elderly populations in hospitals both in Europe and the US have revealed that compliance to VTE prophylaxis can be as low as <50% (14-18).

The groups studied included medical as well as surgical inpatients to show that risk of VTE in the elderly is both underestimated and undertreated with detrimental effects to their well-being.

**Risk Assessment Models**

Traditionally, the assessment of VTE risk encompasses patient and procedure related factors. The type, site, length, urgency and underlying pathology of the operation are combined with individual patient susceptibility to create stratification models and allocation to low-, moderate- and high-risk categories.

Unfortunately, there is no singular algorithm for calculating individual patient risk and correlating these results with expected morbidity/mortality from VTE.

Various models for risk stratification have been proposed in literature, but there is significant variance in their development, and heterogeneity between the published score systems does not allow for direct conclusions.

By far the most widely used is the Caprini score, which stratifies patients in very low, low, moderate and high risk categories after adding points from various factors (19). (Table 2)

It has been externally validated for surgical patients including the critically unwell (20-22).

The estimated baseline risks of VTE are 0.5%, 1.5%, 3.0%, and 6.0% in patients at very low, low, moderate, and high risk for VTE, respectively (20).

The Rogers score is another model developed for surgical patients using data from 183,069 individuals who underwent a variety of procedures (23).

However, it has not been externally validated and has not seen widespread use.

Other scores such as the Khorana score are developed for specific target populations (eg cancer patients) and therefore their use is limited for the general population cohort.

**Methods of Prophylaxis**

**A. Mechanical Prophylaxis**

It is obvious that early mobilisation with return to pre-operative physical activities plays a significant role in preventing venous stasis and subsequently venous thromboembolism. Therefore, elderly patients require physiotherapy support to return to at least their normal ambulation status as soon as possible.

Mechanical prophylaxis aims to prevent VTE by hindering venous stasis in the lower limbs and minimizing oedema in the extremities.

It represents an extremely attractive option for the elderly population belonging to the high bleeding risk category and there is strong evidence supporting its use.

The most common method of mechanical
prophylaxis is elastic compression stockings. They increase blood flow in the deep veins of the legs and their efficacy has been proven in multiple studies from orthopaedic and surgical patients, with reduction in the odds of DVT from 60-72% combined with pharmacological means alone. They can be worn at home and they are very cost-effective. However, they need to be fitted to each patient to avoid constriction of the blood circulation and a subsequent tourniquet effect. Skin changes with necrosis, ulceration, blisters and breaks are unfortunately common in the elderly patients and rare complications such as compartment syndrome and common peroneal nerve palsy must be recognised early (24-25).

Intermittent pneumatic compression stockings utilize air to help promote venous flow in the lower limbs. Apart from the purely mechanical component, their action mechanisms include stimulation of endogenous fibrinolytic mechanisms, reduction in the levels of plasminogen activator inhibitor and increase in the activity of tissue plasminogen activator. The reduction in the odds of distal and proximal DVT has been shown to be around 60% but results failed to demonstrate or to exclude an effect on PE.

There are many different devices available as well as configuration parameters that have been independently studied to assess the optimal pattern for VTE prophylaxis. IPCs are commonly used for patients on the operating table during long operations combined with ES, and frequently represent the only option in obese patients who cannot be fitted with ESs. The drawback is that they are quite bulky and not portable, so they are almost exclusively used in a hospital setting. Even then compliance can be quite poor. Again, skin ulcers and tears need to be avoided by optimal fitting (25-28).

Both methods have been shown to be more effective when combined with pharmacological prophylaxis in the prevention of VTE than either compression or medication alone (25).

### B. Pharmacological Prophylaxis

A variety of pharmacologic agents have been used for pharmacological prophylaxis. Different types of medication include the heparins, Vitamin K inhibitors, antiplatelets and the newer anticoagulants.

Unfractionated and Low-molecular weight heparins, Fondaparinux

Multiple studies have validated the benefit of Unfractionated and Low Molecular Weight Heparin (UH, LMWH) and recently fondaparinux. Low-dose UFH (5000 U subcutaneously 2–3 times daily starting 2 h before the procedure) and LMWH are both effective at reducing the occurrence of DVT in general surgery patients. According to meta-analyses and large clinical trials, low-dose UFH reduces the incidence of DVT from about 25% to 8%, and the incidence of clinically overt and fatal PE by 50% and 90%, respectively (25).

In another meta-analysis, LDUH was associated with an 18% reduction in the odds of death from any cause, 47% reduction in the odds of fatal PE, and 41% reduction in the odds of nonfatal PE, along with a 57% increase in the odds of nonfatal major bleeding (25).

Compared with no prophylaxis, LMWH reduces the risk of clinical PE and clinical VTE by 70%. In addition, LMWH is associated with a possible reduction in the risk of death from any cause. Its use can lead to an approximate doubling of the risks of major bleeding and wound hematoma (25).

Large trials comparing low dose UFH with LMWH in general surgical patients and meta-analysis have suggested that the 2 agents are equally effective.

In meta-analyses the risk for VTE was up to 30% lower in the LMWH groups. However, this difference was not apparent in blinded, placebo trials and there was no proof of beneficial effect of LMWHs Unfractionated Heparin on clinical PE, death from any cause, major bleeding, and wound hematoma, although some studies have shown decreased bleeding risk and a safer profile with LMWHs. Mismetti P, Laporte S, Darmon JY, Buchmuller A, Decousus H. Meta-analysis of low molecular weight heparin in the prevention of venous thromboembolism in general surgery. Br J Surg. 2001; (25, 29-31).

LMWHs however have significant advantages compared to Unfractionated Heparin. They can be administered as a once daily dose, they have predictable pharmacokinetics and are less likely to cause heparin-induced thrombocytopenia. They are therefore the agent of choice in patients with normal renal function and no contraindication to blood thinning medication.

Fondaparinux, a synthetic pentasaccharide, has been approved for prophylaxis of DVT. Heparin-induced thrombocytopenia has not been reported with fondaparinux as it does not interact with platelet function and aggregation, and has a predictable response. Monitoring of PT/PTT is also not required. It has an equal or better effectiveness than currently available agents, no need for laboratory monitoring, and once daily administration.

Studies have shown a potentially higher bleeding risk but there were no fatal events or re-bleeding that required re-operation (25,32).

Aspirin

A meta-analysis in 1994 showed that perioperative acetylsalicylic acid therapy reduces incidence of DVT and PE by 37% and 71% respectively for general surgical patients. However, most of the trials included in this meta-analysis used high dose aspirin, and no trials of low dose aspirin regime exist for general surgery (33).

At the moment aspirin is not indicated as a method of thromboprophylaxis, and its use is reserved for those patients in whom other medications are contra-indicated (25).

Warfarin

Although data are limited for the general surgical cohort, warfarin given postoperatively is likely to be an effective form of prophylaxis although it is reserved as treatment for patients who have already suffered a thrombo-embolic event. Serious issues such as delayed onset of action, need for INR monitoring, complex drug and food interactions and a significantly raised risk of bleeding render it an unappealing choice for prevention alone.

Newer Anticoagulants

The newer anticoagulants, among which rivaroxaban, dabigatran and apixaban, have been approved for treatment of thrombo-
embolism regardless of background, and as pharmacological prevention in orthopaedic surgery (25).

No trials exist for general surgical inpatients. However, their advantages, especially daily oral administration, could present an alternative to daily LMWH for cohorts of surgical patients requiring prolonged out of hospital prophylaxis (25,33).

Renal Disease

Most patients over the age of 70 have a degree of chronic renal insufficiency. Impaired renal function and age have both been proven to be a risk factor for bleeding (Spencer 2008, Lacut 2008), mainly due to changes in drug pharmacokinetics, drug interactions from polypharmacy and an increased risk of falls.

Serum creatinine is an inaccurate indicator of the actual kidney function as its production is decreased with the loss of muscle mass that is common in the elderly. Therefore, calculation of Creatine Clearance (CrCl) with equations such as Cockroft-Gault or MDRD is very important (14).

The anticoagulant of choice in the presence of severe renal impairment remains UFH (34). It has a short half-life of 1-2 hrs, it can be easily reversed with protamine sulphate and its clearance does not depend on renal excretion.

Of the LMWHs, there is evidence that as molecular weight increases, the excretion happens mostly via the reticuloendothelial system (14).

Tinzaparin has been proven to be safe in several studies, independently of renal function. The same stands for Dalteparin prophylactic doses. Many studies prove its efficacy and safety at the widely used dose of 5,000U OD that does not require weight or CrCl adjustment (25,34-37).

Enoxaparin studies suggest that dose reduction needs to be considered in CrCl< 30 while Fondaparinux clearance is directly related to kidney function and dose adjustments are mandatory depending on the degree of renal failure (14).

Measurement of anti-Xa is the only accurate way to assess pharmacokinetics of LMWHs. However it is not routinely performed in clinical practice and it been shown that in the low doses used for prophylaxis, the levels of anti-Xa are actually difficult to correlate with bleeding risk (16,38).

Duration of prophylaxis

Unfortunately, there are only few studies addressing the optimal duration of VTE prophylaxis in the surgical population. From observational/retrospective studies, it has been shown that the risk of thromboembolic events remains high for at least 30 days post-operatively and even up to 3 months after discharge. The ratio can be even 10-50 times higher compared to controls and a retrospective review of medical records for newly discharged surgical patients revealed that more patients presented to hospital with signs and symptoms of VTE in the first 3/12 after their discharge compared to the number of inpatients diagnosed (39,40). In another similar study the mean time to DVT was approximately 65 days after discharge (25).

Currently, there are few guidelines on continued prophylaxis for general surgical patients. Most authors advocate use of mechanical compression methods and blood thinning medication for up to 10 days after high-risk procedures, or until the patients regain their pre-operative mobility. When there is extensive abdominal/pelvic surgery on a background of malignancy, this time is extended to at least 30 days post-op.

Among the high-risk group of those patients undergoing abdominal surgery for cancer, there is evidence that compared with limited-duration prophylaxis (1 week), extended-duration prophylaxis (4 weeks) with LMWH provides additional protection from nonfatal VTE, without an important increase in the risk of nonfatal major bleeding complications (25,41).

In other reviews, the incidence of overall VTE after major abdominal or pelvic surgery was 14.3% in the control vs 6.1% in the patients receiving out-of-hospital LMWH. Prolonged thromboprophylaxis with LMWH was also
associated with a statistically significant reduction of even the incidence of symptomatic VTE from 1.7% to 0.2% in patients receiving prolonged thromboprophylaxis. There was no significant change in the risk of bleeding (42-44).

It can therefore be inferred that extended prophylaxis is beneficial for surgical patients with high risk for VTE and especially those suffering from malignancy.

**Contraindications to Prophylaxis**

The absolute contraindications for drug thromboprophylaxis are those already known for the general adult population. Untreated haemophilia and other haemorrhagic disorders, active bleeding or high bleeding risk (peptic ulcer, recent cerebral haemorrhage, severe hypertension, severe liver disease), thrombocytopenia with platelets <60 × 10^9 /L, a history of heparin-induced thrombocytopenia, and hypersensitivity to heparin are all contraindications to treatment.

Age itself has been proven to be a significant predisposing factor for bleeding and bleeding-related complications for patients receiving oral anticoagulants (7,10,14).

While the 3-month risk of major bleeding usually ranges from 2% to 3% among patients receiving oral anticoagulants, this risk doubles inpatients aged 65 years. The risk of intracerebral bleeding also doubles in patients aged 80 years or above.

The increased bleeding risk in the elderly can be explained by several factors: a lower metabolic clearance of vitamin K antagonists, multiple comorbidities, polypharmacy, pathological changes in cerebral vessels and an increased risk for falls.

Evidence suggests that bleeding from antithrombotic agents is a strong predictor of mortality and reduces the overall benefits of VTE prophylaxis in hospitalized patients (14, 45-48).

Guidelines combine the thromboembolic and bleeding risk of patients to create suggestions about optimal VTE prophylaxis with minimal side effects (Table 3).

**Conclusions**

There is no doubt that elderly surgical patients have a high risk of VTE and subsequent death from PE, attributed to the aging process itself but also their multiple associated comorbidities. However, because of low clinician awareness of this risk or excessive fear that anticoagulation will lead to fatal bleeding, almost half do not receive the appropriate prophylaxis.

LDUH: Low dose unfractionated heparin, LMWH: Low molecular weight heparin, ES: Embolic stockings, IPC: Intermittent Pneumatic Compression
required by their calculated risk.

Existing guidelines suggest that LMWHs in combination with mechanical prophylaxis yield the best results in terms of VTE prevention. However, it is the combination of thromboembolic and bleeding risks for each individual that ultimately guides the decision on method of prophylaxis.

Newer pharmacological agents such as fondaparinux and NOACs have been introduced for surgical and orthopaedic patients, but especially the latter need further studies to establish themselves as a standard for prophylaxis in the general surgical population.

Clinicians need to be aware of the existing risk for VTE both when the patient is hospitalized but also after their discharge. It has been proven beyond doubt that VTE risk and subsequent mortality remain high in a cohort of surgical patients for a long time after their initial hospitalisation.

Conflicts of Interest

No declarations by the authors.
